**CPHLN Recommendations on
Laboratory Evidence of SARS CoV Infection**

Table 1: Laboratory Evidence of SARS CoV Infection

Lab test	Strength of evidence	Additional lab tests	Comments
<p>Detection of SARS-CoV RNA by RT-PCR on at least two different clinical samples</p> <p>Initial clinical samples should be aliquoted in 2-3 different tubes prior to extraction. An initially positive sample should be confirmed using one of the back-up tubes.</p> <p>Ideally two different sets of primers should be used to confirm the diagnosis.</p>	<p>Sensitivity and specificity of these tests is currently unknown.</p> <p>Testing of different aliquots of a given sample and that of a second clinical sample (from a different site, or the same site on a different day) should reduce the frequency of false positive results.</p> <p>Testing in a second independent laboratory is recommended to verify PCR results.</p>		<p>Nested RT-PCR is highly susceptible to contamination</p>
<p>Seroconversion by IFA or ELISA</p>	<p>Probably good during known cluster of cases, but exact sensitivity and specificity are still unknown.</p>	<p>Collect second serum sample 14 days after the initial serum sample (NOTE: Some patients may take 21 or more days to seroconvert. If there is no detectable seroconversion after 21 days, a specimen should be taken at 28 days.)</p>	<p>Seroconversion should not be used to define the first case of a possible cluster.</p> <p>Confirmation of seroconversion to SARS CoV by Plaque Reduction Neutralization (PRN) is strongly recommended.</p>
<p>Positive Viral Culture</p>	<p>Excellent</p>		<p>Should only be done in a certified Level 3 laboratory</p>
