### Note of Appreciation

Canada owes the success of its statistical system to a long-standing partnership between Statistics Canada, the citizens of Canada, its businesses, governments and other institutions. Accurate and timely statistical information could not be produced without their continued cooperation and goodwill.

# **SYMBOLS**

The following standard symbols are used in Statistics Canada publications:

- .. figures not available.
- ... figures not appropriate or not applicable.
- nil or zero.
- amount too small to be expressed.
- p preliminary figures.
- r revised figures.
- x confidential to meet secrecy requirements of the Statistics Act.

These tables and explanatory text were prepared under the direction of :

### INTRODUCTION

A life table represents a universally accepted demographic or actuarial model that synthesizes the mortality experience of a population, in a clear and concise manner, and enables comparative measures of expected longevity. The model used to construct these tables assumes that a hypothetical cohort of 100,000 individuals born at the same moment in time is subject to the age-sex-specific mortality rates experienced by an actual population during a specific time period.

This report contains life tables constructed from the age-sex-specific mortality rates observed for Canada, the provinces and the territories in the 1995-1997 period. It also explains the methods used to produce these tables, and reproduces the formulae used to derive the estimates. Life tables for the first year of life have been produced separately, by sex, for Canada as a whole. Complete life tables by single year of age, for both males and females, have been generated for Canada and for each province except Prince Edward Island. Because of their small populations and low death counts, abridged life tables with five-year age groups have been produced for both Prince Edward Island and all territories combined, by sex.

### 1. INPUT DATA

Creation of the life tables involved three major steps: gathering input data, calculation of mortality rates, and calculation of other life table values. This section describes the first step. For the construction of the 1995-1997 life tables, the following input data were required, by sex, for Canada, the provinces and the territories.

Input data for the infant life tables (i.e. for the first year of life):

- The total number of births in 1995 and 1996.
- The number of births by month in 1994 and in 1997.
- The number of infant deaths observed during the 1995-1997 period, aggregated by life-span period (i.e. days, weeks and months of life see Table 1a).
- The value of T, by sex, from the corresponding complete life table for Canada (see formulae (29.1) to (29.4)).

### Input data for the complete life tables:

- The number of deaths of children aged 0 to 4 years, observed during the 1995-1997 period, by single year of age, year of birth and year of death.
- January 1 population counts, by sex, for the years 1995 to 1998, by single year of age for ages 0 through 4 years.
- Separation factors at ages 0 to 4 years (see appendix 1).
- The number of deaths observed during the 1995-1997 period, by single year of age up to 104 years, and a final group of deaths of persons aged 105 and older.
- The number of deaths of persons aged 87 and older, by single year of age, observed during the 1995-1997 period (see the Coale and Kisker model, section 2.1.6).
- July 1, 1996 population counts, by five-year age groups, for ages 0-4 to 100-104 years, and a final age group consisting of persons aged 105 and older.

### Input data for the abridged life tables:

- The total number of births recorded during the 1994-1997 period.
- The total number of deaths observed during the 1995-1997 period for the following age groups: infants under 1 year (age 0), ages 1-4 years combined, five-year age groups for ages 5-9 to 95-99 years, and a final group of deaths of persons aged 100 and older.
- July 1, 1996 population counts for the following age groups: under 1 year (age 0), ages 1-4 years combined, five-year age groups for ages 5-9 to 95-99 years, and a final age group consisting of persons aged 100 years and older.
- Separation factors at ages 0 and 1-4 years combined.

# Input data for the separation factors:

- The number of deaths observed in the 1995-1997 period of children aged 0 to 4 years by death group. The term 'death group' refers to a dichotomous variable derived from the year of birth, year of death and age at death. The death group indicates whether or not an individual had a birthday (or was born - in the case of an infant death) in the calendar year during which their death occurred. See also Appendices 1 and 2.

### Data sources:

- Birth and death data by province or territory of residence were compiled by Health Statistics Division, Statistics Canada.
   These data were extracted from birth and death registrations submitted to Vital Statistics registrars in the province or territory in which the event occurred.
- Population counts, produced by Demography Division, Statistics Canada, are estimates of the July 1, 1996 population, based on the 1996 Canadian Census of Population. These counts include non-permanent residents, and are adjusted for net census under-coverage.<sup>1</sup>

Adjusted population estimates are generally higher than unadjusted estimates. The use of higher adjusted population estimates results in slightly lower mortality rates, which in turn generate slightly higher life expectancy values than would otherwise have been calculated.<sup>2</sup>

For Canada as a whole, the complete life table values are shown to age 109 for each sex. For the provinces, these tables have been truncated at ages ranging from 99 to 109 years, depending on the quality of the source data. For Prince Edward Island and the territories (i.e. Yukon, Northwest Territories and Nunavut combined), abridged estimates are presented for five-year age groups, up to age 95-99 years, with a final group for ages 100 years and older.

# 2. METHODOLOGY

The methodology followed in constructing the 1995-1997 life tables is the same as that employed previously in producing the set of life tables for the years 1990-1992,<sup>3</sup> but with two major changes. These changes in methodology apply to the production of estimates for the extreme ends of the age range in the complete life tables: (1) a model was used to estimate mortality rates for the very advanced ages (88 years and older), and (2) January 1 population counts of children aged 0 to 4 years were used instead of birth counts of the previous year to calculate mortality rates for the very young (ages 0 through 4 years). Variance estimation for q, has been included, in order to produce coefficients of variation of life expectancies, e.

Other changes of a lesser nature in methodology have been made. The value of  $q_x$  is not set to 1 for the oldest age published in the complete life tables, but rather is reported as the probability of death estimated for that single year of age. Where data quality permitted, each complete life table was expanded up to age 109 years. The abridged life tables extend to age "100 years plus" rather than to "90 years plus" as in the 1990-1992 life tables.

All calculations were carried out using the Statistical Analysis System (SAS)<sup>4</sup> software. Full decimal precision was maintained until the Sirken rounding procedure,<sup>3</sup> used in the 1990-1992 life tables, was applied to the data at the end of the calculations. The Sirken rounding procedure sets the values of  $d_x$  and  $L_x$  equal to the difference between two consecutive rounded values of  $l_x$  and  $T_x$ , respectively. In this way, both of the following basic relationships are preserved in the published tables:  $l_x$  -  $d_x$  =  $l_{x+1}$  and  $l_x$  -  $l_x$  =  $l_x$  (see section 3 for an explanation of these symbols).

The following sections describe methodological issues specific to each set of tables.

### 2.1 Complete Life Tables

The procedure employed in the construction of the complete life tables is essentially that described by Greville in *United States Life Tables and Actuarial Tables*, 1939-1941.<sup>5</sup> The same methodology was used to produce the earlier sets of life tables for Canada beginning with the years 1970-1972.<sup>3</sup>

The principal values of all life tables are the  $_nq_x$  values. They represent the probability for persons of exact age "x" of dying within the interval from the beginning of age "x" to the beginning of age "x+n". In other words,  $_nq_x$  is the probability of death for the hypothetical cohort of 100,000 people in the age interval [x, x+n). For the complete life tables, the age interval is one year, i.e., n = 1. In this case, the left subscript is sometimes omitted and the life table mortality rate is referred to simply as  $q_x$ .

Sections 2.1.1 to 2.1.6 show how the  $q_x$  values were calculated. The calculation of other life table values is explained in section 3.

### 2.1.1 Ages 0 to 4 years

By definition,

(1) q is the probability that a person aged exactly x years old will die before reaching exact age x+1,

and, since  $p_v = 1 - q_v$ ,

(2) p<sub>v</sub> is the probability that a person aged exactly x years will survive to exact age x +1.

By commonly-used notation,<sup>6,7</sup> the probability of survival defined in (2) can be expressed in the form of the product of two other probabilities of survival:

(3)  $p_x = ({}_{\alpha}p_x)({}_{\delta}p_x),$ 

where

x denotes the age from 0 to 4 years,

 $_{\alpha}$ p $_{x}$  is the probability that a person aged exactly aged x years old will survive to the end of the calendar year in which age x was attained, and

 $_{\delta}p_{x}$  is the probability that a person alive at the end of the calendar year in which age x was attained will survive to exact age x+1.

From this,

(4) 
$$_{\alpha}p_{x} = P_{x}' / E_{x},$$

where

P<sub>x</sub>' is the number of persons who attained age x during the three-year period of observation, in this case, 1995-1997, and who were alive at the end of the year in which exact age x was attained, and

E<sub>v</sub> is the number of persons who attained age x during the period 1995-1997.

Similarly,

(5) 
$$_{\delta}P_{x} = E_{x+1} / P_{x}^{"},$$

where

E<sub>x+1</sub> is the number of persons who attained age x+1 during the period 1995-1997, and

P<sub>x</sub> is the number of persons alive at the end of the calendar year in which age x was attained and whose (x+1)<sup>th</sup> birthday falls in the period 1995-1997.

Therefore, q is calculated by the following equation,

(6) 
$$q_x = 1 - (P_x'/E_x) (E_{x+1}/P_x''),$$

for x = 0 to 4 years.

Note: Uppercase letters P and E are not to be confused with lowercase letters p and e that designate, respectively, the proportion of individuals surviving, and the average remaining years of life. For more explanations on how P and E were calculated, see Appendix 2.

In the provincial complete life tables, values of  $q_0$  to  $q_4$  were verified to ensure that they decreased monotonically. Generally  $q_0 > q_1$ , so ensuring that the series from  $q_0$  to  $q_4$  decreased monotonically required adjustments to the sub-series  $q_1$  through  $q_4$  only. This adjustment proceeded as follows. From definition (1) above, provincial survival probability values  $p_x$  were calculated from the  $q_x$ , and new  $p_x$  were obtained by applying national survival rates at ages 1 to 4 to the geometric mean of provincial survival rates. The new  $p_x$  is calculated as follows:<sup>8</sup>

(7)

$$(\text{new p}_{x}) = \frac{(\text{national p}_{x}) \begin{bmatrix} 4 \\ \prod_{k=1}^{4} (\text{old p}_{k}) \end{bmatrix}^{\frac{1}{4}}}{\begin{bmatrix} 4 \\ \prod_{k=1}^{4} (\text{national p}_{k}) \end{bmatrix}^{\frac{1}{4}}}$$

for x = 1 to 4 years,

where "national  $p_x$ " is the sex-specific national survival probability at age x, and "old  $p_k$ " is the previously-calculated sex-specific provincial survival probability at age k. New values of  $q_x$  were then calculated from the new values of  $p_x$ . An attractive feature of this procedure is that both the old and the new values of  $p_x$  (and thus  $q_x$ ) produce the same number of survivors at age 5. Text Table 1 shows an example of this calculation for males in Nova Scotia, starting from a cohort of 100,000 live births.

Text table 1. Adjustment of mortality rates, ages 1-4 years, Nova Scotia males

Age x	Expected number of deaths using old $q_x$	Expected number of deaths using new $q_x$	
0	497	497	
1	53	40	
2	11	29	
3	19	23	
4	27	18	
umber of survivors at age 5 years	99,393	99,393	

Text Table 1 shows the effect of the adjustment of probabilities of death among Nova Scotia males aged 1 to 4 years. The new mortality rates at ages 1 to 4 years decrease in a monotonic fashion, and the number of survivors at age 5 remains the same for the old and the new mortality rates.

This new procedure requires that  $q_0$  through  $q_4$  form a monotonically decreasing sequence by sex at the national level, as did the procedure used in the 1990-1992 life tables publication. An adjustment had to be made, however, to the value of  $q_3$  for females at the Canada level to achieve such a sequence; the observed  $q_3$  was replaced by the average of the values of  $q_2$  and  $q_4$ .

Formula (7) was applied to the data for males in all provinces except Ontario, where this adjustment was unnecessary. The same adjustment needed to be made to the data for females in all provinces except Nova Scotia. Furthermore, this procedure was extended for males up to age eight in Newfoundland in order to produce a monotonically decreasing sequence of mortality rates  $q_a$  through  $q_a$ .

For females in Manitoba and Nova Scotia, as well as for males in New Brunswick and British Columbia, the observed sequence of mortality rates  $q_0$  through  $q_4$  decreased monotonically. This adjustment procedure produced a new sequence of mortality rates  $q_1$  through  $q_4$  that provided a smoother fit; the adjusted  $q_1$  through  $q_4$  were retained over the original values.

# 2.1.2 Ages 7, 12, 17, ..., 87 years

These ages are referred to as pivotal ages because they represent the middle point of the typical age groups 5-9 years, 10-14 years, 15-19 years, etc. The basic equation, also known as the actuarial method, is

(8) 
$$q_x = 2 m_x / (2 + m_x),$$

where x = 7, 12, 17, ..., 87,

and m, is the central death rate, defined as follows:

$$(8.1)$$
  $m_{v} = (D_{v} / 3) / P_{v}$ 

where  $D_x$  and  $P_x$  are defined by King's formula:3

$$D_x = 0.216 D_x' - 0.008 (D_{x-5}' + D_{x+5}'),$$

$$P_x = 0.216 P_x' - 0.008 (P_{x-5}' + P_{x+5}'),$$

in which

D' is the sum of deaths observed in the period 1995-1997 at ages x-2, x-1, x, x+1 and x+2,

 $P_x$  is the sum of the population estimates at ages x-2, x-1, x, x+1 and x+2.

Although there is uncertainty about the quality of the population estimates above age 90, population counts by single year of age were used for ages up to 102 years, a limit deemed to be acceptable according to research conducted by Bourbeau and Lebel.<sup>9</sup> Doing so avoided the problem encountered in the 1990-1992 publication, in which the last age group of the population was 90 years and older. As a result,  $D_{92}'$  and  $P_{92}'$ , as calculated, were larger than their true values, and the final effect on  $m_{87}$  and  $q_{87}$  was considered to be "unknown" in the 1990-1992 publication.

Following the example of Chiang, 10 the variance of q, was estimated as:

(9) 
$$\operatorname{var}(q_x) = q_x^2 (1 - q_x) / D_x^*$$

where

D\* is the average number of deaths at age x over the 3-year period 1995-1997,

D\* = (1/3) [ (# deaths at age x in 1995) + (# deaths at age x in 1996) + (# deaths at age x in 1997) ].

# 2.1.3 Ages 92, 97, 102, 107 and 112 years

At pivotal ages 92 to 112 years, the value of q, was obtained by extrapolation using Nagnur's "Equation (14)".11

(10) 
$$q_x = min \{ (4 q_{x-5} - 6 q_{x-10} + 4 q_{x-15} - q_{x-20}), 1 \},$$

and the corresponding variance estimation (ignoring covariances):

(10.1) 
$$\operatorname{var}(q_x) = 16 \operatorname{var}(q_{x-5}) + 36 \operatorname{var}(q_{x-10}) + 16 \operatorname{var}(q_{x-15}) + \operatorname{var}(q_{x-20}),$$

for x = 92, 97, 102, 107 and 112.

# 2.1.4 Intermediate Ages from 13 to 106 years

Intermediate q values were derived from the q values at pivotal ages according to Karup-King's third-difference tangential formula subject to an upper bound of 1. This formula preserves the q values calculated so far at pivotal ages.

(11) 
$$q_{x+1} = min \{ (-0.064 q_{x-5} + 0.912 q_x + 0.168 q_{x+5} - 0.016 q_{x+10}), 1 \},$$

(12) 
$$q_{x+2} = min \{ (-0.072 q_{x-5} + 0.696 q_x + 0.424 q_{x+5} - 0.048 q_{x+10}), 1 \},$$

(13) 
$$q_{x+3} = min \{ (-0.048 q_{x-5} + 0.424 q_x + 0.696 q_{x+5} - 0.072 q_{x+10}), 1 \},$$

(14) 
$$q_{x+4} = min \{ (-0.016 q_{x-5} + 0.168 q_x + 0.912 q_{x+5} - 0.064 q_{x+10}), 1 \},$$

where x = 12, 17, 22, ..., 102.

Variance estimation follows the strategy of the previous section. For example, to obtain  $q_{106}$ , the pivotal age values  $q_{97}$ ,  $q_{102}$ ,  $q_{107}$  and  $q_{112}$  are required.

# 2.1.5 Intermediate Ages from 5 to 11 years

Different formulae were used for the intermediate ages between 5 and 11 years. They are adapted from Nagnur, with a few changes in the signs.<sup>11</sup>

For ages 8 to 11, the following set of four equations was derived from Jenkins' fifth difference osculatory non-reproducing formula:

(15) 
$$q_8 = -(217 q_2 - 3,892 q_7 - 966 q_{12} + 140 q_{17} + q_{22}) / 4,500,$$

(16) 
$$q_9 = -(296 q_2 - 3,056 q_7 - 1,968 q_{12} + 220 q_{17} + 8 q_{22}) / 4,500,$$

(17) 
$$q_{10} = -(279 q_2 - 2,124 q_7 - 2,862 q_{12} + 180 q_{17} + 27 q_{22}) / 4,500,$$

(18) 
$$q_{11} = -(208 q_2 - 1,228 q_7 - 3,054 q_{12} + 40 q_{17} + 64 q_{22}) / 4,500.$$

This produces a smoother curve than Karup-King's formula which was used for the intermediate ages from 13 to 105 years. 12

Finally, for ages 5 and 6:

(19) 
$$q_5 = -0.3 q_3 + q_4 + 0.5 q_7 - 0.2 q_8$$

(20) 
$$q_6 = -0.2 q_3 + 0.5 q_4 + q_7 - 0.3 q_8$$

Note that since these formulae use  $q_2$ ,  $q_3$  and  $q_4$ , and since some adjustments are made to these estimates in order to ensure that the series  $q_0$  through  $q_4$  decreases monotonically, it was necessary to determine whether to use the unadjusted or the adjusted values of  $q_2$  through  $q_4$  in the above formulae. For males in British Columbia and New Brunswick, the values of  $q_5$ ,  $q_6$  and  $q_8$  through  $q_{11}$  were recalculated based on the new adjusted values of  $q_1$  through  $q_4$ . In the case of Newfoundland males, only the values of  $q_5$  through  $q_{11}$  were recalculated because the procedure described in Section 2.1.1 had been extended to produce the values of  $q_1$  through  $q_8$ . For all other province and sex combinations, the values of  $q_5$ ,  $q_6$  and  $q_8$  through  $q_{11}$  were calculated based on the original unadjusted values of  $q_1$  through  $q_4$ .

# 2.1.6 Model-based Replacement Estimates of National and Provincial Mortality Rates at Advanced Ages

As noted in Section 2.1.2, the quality of population estimates becomes very uncertain at advanced ages. Coale and Kisker<sup>13</sup> found significant problems in the accuracy of population estimates for advanced ages in the U.S., in part due to misreporting of age. As a result, they developed a model-based alternative for estimating the central death rates for advanced ages. This method produces a more realistic evolution of mortality rates at very old ages, since recent observations show a deceleration in the rate of increase of mortality rates. The method follows these steps:

Compute age-specific central death rates for x = 82, 83, ..., 86 years:

$$M_v = D_v^* / P_v$$

where, as in Section 2.1.2 above, D\* is the average number of deaths at age x over the 3-year period 1995-1997.

Take the average of  $M_{\downarrow}$  around x = 84:

$$M_{avg} = (1/5) (M_{82} + M_{83} + M_{84} + M_{85} + M_{86});$$

Define two constants (K<sub>85</sub> and S) next:

$$K_{85} = (1/4) \log(M_{86} / M_{82});$$

$$S = (-1/325) [ log(M_{avg} / M_{110}) + 26 K_{85} ].$$

Set  $M_{110} = 1$  for males and 0.8 for females.

For age values of x from 87 years through 117 years, the new CK (Coale-Kisker) estimates for age-specific death rates are calculated as follows:

(21) 
$$M_{CK}(x) = M_{avg} EXP\{ (x - 84)[ K_{85} + (x - 85)(S/2) ] \}.$$

For ages (87 years)  $\leq$  x  $\leq$  (117 years), the new CK estimates for the probability of dying before the next birthday were calculated as in the basic equation (8):

(22) 
$$Q_{CK}(x) = (2 M_{CK}(x)) / (2 + M_{CK}(x)).$$

The variance estimation on the new CK estimates used  $Q_{CK}(x)$  in place of  $q_x$  in Formula (9).

It was then necessary to decide at what age to replace the value of  $q_x$  calculated from observed data by Equation (8) with the new model-based value of  $Q_{CK}(x)$ . For the province-level estimates, the value of  $q_x$  was kept up to the pivotal age x = 87 years, and then the value of  $Q_{CK}(x)$  was used starting with x = 88 years. At the national level, however, the value of  $q_x$  was kept up to x = 92 years, and then replaced with the value of  $Q_{CK}(x)$  starting at x = 93 years.

This raised another question, however. Recalling the computation of q values for intermediate ages in Section 2.1.4, it can be seen, for example, that the computation of  $q_{88}$  through  $q_{91}$  requires the use of  $q_x$  at the pivotal ages 77, 82, 87, 92 and 97. Now that new values of  $q_x$  at age 97 years at the national level, and at ages 92 and 97 years at the provincial level have been calculated, the decision needed to be made whether to re-compute the values of  $q_{88}$  through  $q_{91}$  with these new pivotal age  $q_x$  values. Since the smoothness of the  $q_x$  series, produced with the original  $q_{88}$  through  $q_{91}$  values combined with the new pivotal age  $q_x$  values, was satisfactory, no further adjustments were made.

Despite this strategy, there were still two province and sex combinations that required further manual adjustment in order to avoid "bumps" in the  $q_x$ -series. For males in New Brunswick and females in Newfoundland, the average of  $q_{87}$  and  $Q_{CK}(89)$  was calculated to obtain a new  $q_{88}$ . For the variance estimation, note that:

$$q_{88,new} = (1/2) q_{87} + (1/2) Q_{CK}(89),$$

then, if there is no covariance between  $q_{87}$  and  $Q_{CK}(89)$ ,

$$var(q_{88 \text{ new}}) = (1/4) var(q_{87}) + (1/4) var(Q_{CK}(89)).$$

A more conservative strategy was chosen, however, that of using the larger of  $var(q_{88,new})$  and the original  $var(q_{88})$  estimate; this turned out to be the original  $var(q_{88})$  estimate in each case.

# 2.2 Abridged Life Tables

In an abridged life table, the move from one row to the next usually involves a gap of more than a single year of age. For this reason, in this section the notation  $_{n}q_{x}$  is used for the probability that a person of exact age x years will die before reaching exact age x+n.

Abridged life tables were required for the province of Prince Edward Island and for all northern territories combined because their smaller populations prevented meaningful construction of complete life tables for these areas. Hence, following the procedure adopted for the 1970-1972 life tables, abridged life tables were constructed separately for males and females. The methodology has been explained in a technical paper by Silins and Zayachkowski. Whereas the life tables for the 1990-1992 publication followed this methodology closely, some enhancements have been made for this 1995-1997 publication.

The first step was to define 22 age groups: 0 years, 1-4 years, 5-9 years, 10-14 years, 15-19 years, 20-24 years, 25-29 years, 30-34 years, 35-39 years, 40-44 years, 45-49 years, 50-54 years, 55-59 years, 60-64 years, 65-69 years, 70-74 years, 75-79 years, 80-84 years, 85-89 years, 90-94 years, 95-99 years, and 100 years and older.

Next, the following calculations were performed at the provincial level:

(23) 
$$m_v = D_v / (3 P_v)$$
,

where

- m, is the age-specific central death rate,
- x designates the lower bound of each age group: x = 0, 1, 5, 10, ..., 85, 90, 95, 100 years,
- D<sub>v</sub> is the number of deaths in the age group starting with age x during the period 1995-1997, and
- P<sub>x</sub> is the population count in the age group starting with age x on July 1, 1996, adjusted for net census under-coverage and including non-permanent residents (see Section 1).

(24) 
$$F_0 = g_2 / (g_1 + g_2)$$
,

where

- F<sub>0</sub> is the separation factor at age 0 years, and
- g<sub>k</sub> is the number of deaths at age 0 years in death group k; group 1 contains individuals who died in the calendar year in which they were born; group 2 contains individuals who died in the calendar year following their birth year (see Appendix 1 for more details).

As explained in detail in Appendix 1, separation factors were calculated separately by sex, but not necessarily by province. Unlike the calculation of the separation factors for the complete life tables (shown in Table A1 in Appendix 1), data for PEI and the northern territories were included in the computation of separation factors for the abridged life tables. For PEI, separation factors were calculated with data for all four Atlantic provinces combined. For the three northern territories combined, separation factors were calculated with data for the territories in combination with all of western Canada (from Manitoba westward).

(25.1) 
$$_{1}q_{0} = D_{0} / [B_{94-96} (1 - F_{0}) + B_{95-97} (F_{0})],$$

where

- D<sub>o</sub> is the number of deaths at age 0 years observed during the period 1995-1997,
- B<sub>94-96</sub> is the total number of births observed during the period 1994-1996,
- $B_{\mbox{\tiny os.o7}}$   $\;\;$  is the total number of births observed during the period 1995-1997.

Formula (25.1) for  $_1q_0$  represents a better estimation of  $q_0$  than that used in the 1990-1992 life tables, because it takes into account variations in the annual number of births during the period.

(25.2)  $_{4}q_{1} = m_{1} / \beta_{1}$ , known as Greville's method,<sup>2</sup>

where

m, is defined by Equation (23), and

$$\beta_1 = (1 / w_1) + m_1 [(1 - F_1) + (w_1/12) (m_1 - k)],$$

in which

 $w_1 = 4$  (the width of the age 1 - 5 years interval),

 $F_1$  is the separation factor for the 1 - 4 years age group, calculated by sex and by region as explained above, and

$$k = (1/45) \ln (m_{85} / m_{40}).$$

(25.3)  $_{5}q_{x} = m_{x} / \beta_{x}$ ,

x = 5, 10, ..., 85, 90, 95,

m, is defined by Equation (23), and

$$\beta_x = (1 / w_x) + m_x [0.5 + (w_x/12) (m_x - k)],$$

in which

where

 $w_y = 5$  (the width of age intervals for x = 5 through 95), and

$$k = (1/45) \ln (m_{85} / m_{40}).$$

For all values of "q" up to this point, the following variance estimate is used:

$$(25.4) \text{ Var}(q_x) = {}_{n}q_x^2 (1 - {}_{n}q_x) / D_x.$$

$$(25.5) q_{100} = 1$$

Note that  $var(q_{100}) = 0$ , whether because the value of  $q_{100}$  is set to a constant, or whether the variance estimation formula above is used. An unfortunate consequence is that the value of  $var(e_{100}) = 0$ .

- (26.1)  $I_0 = 100,000$
- (26.2)  $_{1}d_{0} = _{1}q_{0} I_{0}$
- (27.1.1)  $I_1 = I_0 {}_1d_0$
- (27.1.2)  $_{4}d_{1} = _{4}q_{1} I_{1}$
- (27.2.1)  $I_5 = I_1 {}_4d_1$
- (27.2.2)  $_{5}d_{5} = _{5}q_{5}$   $I_{5}$
- (27.3.1)  $I_x = I_{x-5} {}_{5}d_{x-5}$  for x = 10, 15, ..., 100
- (27.3.2)  $_{5}d_{x} = _{5}q_{x} I_{x}$  for x = 10, 15, ..., 100
- (28.1)  $_{1}L_{0} = I_{0} (1 F_{0})_{1}d_{0}$
- (28.2.1)  $_{4}L_{_{1}} = _{4}d_{_{1}}/_{_{4}}m_{_{1}}$  if  $_{4}m_{_{1}} \neq 0$

$$(28.2.2)$$
  $_{4}L_{1} = 4 I_{1}$  if  $_{4}m_{1} = 0$ 

(28.3.1) 
$${}_{5}L_{5} = {}_{5}d_{5}/{}_{5}m_{5}$$
 if  ${}_{5}m_{5} \neq 0$ 

$$(28.3.2)$$
 <sub>5</sub>L<sub>5</sub> = 5 I<sub>5</sub> if <sub>5</sub>m<sub>5</sub> = 0

(28.4.1) 
$${}_{5}L_{x} = 2.5 (I_{x} + I_{x+5}) + (5/24) ({}_{5}d_{x+5} - {}_{5}d_{x-5})$$
  
if  ${}_{5}m_{x} \neq 0$ , for  $x = 10, 15, ..., 90$ 

(28.4.2) 
$$_{5}L_{y} = 5 I_{y} \text{ if } _{5}m_{y} = 0, \text{ for } x = 10, 15, ..., 90$$

$$(28.5.1)$$
  $_{5}L_{95} = _{5}d_{95}/_{5}m_{95}$  if  $_{5}m_{95} \neq 0$ 

$$(28.5.2)$$
  $_{5}L_{95} = 5 I_{95}$  if  $_{5}m_{95} = 0$ 

(28.6.1) 
$$L_{100+} = d_{100+} / m_{100+} \text{ if } m_{100+} \neq 0$$

(28.6.2) 
$$L_{100+} = 4 I_{100+}$$
 if  $m_{100+} = 0$ 

$$(29.1)$$
  $T_{100+} = L_{100+}$ 

(29.2) 
$$T_x = T_{x+5} + {}_{5}L_x$$
 for  $x = 95, 90, ..., 5$  (values of x descending)

(29.3) 
$$T_1 = T_5 + L_1$$

(29.4) 
$$T_0 = T_1 + L_0$$

(30) 
$$e_x = T_x / I_x$$
 for  $x = 0, 1, 5, 10, ..., 100$ 

For the variance estimation of e,, the procedure illustrated in Chiang10 for the variance estimation of q, was followed, using the formula:

(30.1) 
$$\operatorname{var}(e_x) = \frac{1}{I_x^2} \sum_{i=x}^{N-1} I_i^2 [(1 - f_0)_{W_i} + e_{i+1}]^2 \operatorname{var}(q_x)$$

where,

N is the total number of rows in the table, and

w, is the width of the age interval for which x is the lower bound.

(31) 
$$p_x = 1 - q_x$$
;  $n = 1$  for  $x = 0$ ;  $n = 4$  for  $x = 1$ ;  $n = 5$  for  $x = 5, 10, ..., 95$ 

After the above calculations were performed, values were rounded according to Sirken's method, which consists of the following steps:

- round I and T to the nearest integer, for x = 0, 1, 5, 10, ..., 100

- set  ${}_{1}d_{0} = I_{0} I_{1}^{x}$ set  ${}_{4}d_{1} = I_{1} I_{5}$ set  ${}_{5}d_{x} = I_{x} I_{x+5}$  for x = 5, 10, ..., 95

- $set_{5}^{4}L_{0} = T_{0}^{90} T_{1}$   $set_{4}L_{1} = T_{1} T_{5}$   $set_{5}L_{x} = T_{x} T_{x+5} \text{ for } x = 5, 10, ..., 95$

### 2.3 Infant Life Tables

This is the sixth time that sets of life tables for subdivisions of the first year of life have been produced for Canada. As was the case with respect to the 1990-1992 life tables, the method described in detail by Sirken<sup>15</sup> was employed in constructing these tables. The basic underlying assumption in the production of these tables is that a closed cohort of 100,000 live births is subject to the mortality rates of each subdivision of one year of age, but for the first year of life only.

Vital statistics data files of deaths (years 1995 to 1997) and births (years 1994 to 1997) were used to produce infant life tables. The age at death was calculated as the number of completed days or months of life. For deaths occurring within 24 hours of birth, the age was reported as the number of minutes or hours lived. For these deaths, age was coded as 0 days (i.e., less than one day lived). Other infant deaths were coded as the number of days or months lived as reported on the death data files.

The following 21 subdivisions of the first year of life were used to calculate probabilities of death in infant life tables: the first seven days, weeks 2 to 4, and months 2 to 12. In addition to those subdivisions, infant life tables include two more rows: one for the first week (summing deaths from the first seven days) and one for the first month (summing deaths from the first four weeks).

Text Table 2. Subdivisions of the first year of life

Subdivision Number (s)	Age Interval
(s)  1 2 3 4 5 6 7 8 9 10 11 12 13 14 15 16 17 18 19 20	≥ 0 and < 1 day ≥ 1 and < 2 days ≥ 1 and < 2 days ≥ 2 and < 3 days ≥ 3 and < 4 days ≥ 4 and < 5 days ≥ 5 and < 6 days ≥ 6 and < 7 days ≥ 1 and < 2 weeks ≥ 2 and < 3 weeks ≥ 3 and < 4 weeks ≥ 4 weeks and < 2 months ≥ 2 and < 3 months ≥ 3 and < 4 months ≥ 3 and < 4 months ≥ 4 and < 5 months ≥ 5 and < 6 months ≥ 5 and < 6 months ≥ 6 and < 7 months ≥ 7 and < 8 months ≥ 8 and < 9 months ≥ 9 and < 10 months ≥ 9 and < 10 months
21	≥ 11 and < 12 months

### 2.3.1 Probabilities of Death

The probabilities of death for the 21 subdivisions of the first year of life were calculated in two steps, as follows.

### Step 1: Calculate the number of births exposed to the risk of death

For each of the 21 subdivisions of the first year of life,  $\beta_s$ , the number of births in subdivision s that were exposed to the risk of death, was calculated from the following formulae. The formulae are attributable to Sirken and are expressed differently but equivalently by other authors.<sup>7,11,15</sup>

For subdivision 21 (corresponding to the age interval 11-12 months):

$$(32) \quad \beta_{21} = \left\{ \begin{array}{l} B_{1994,1} + \sum\limits_{m=2}^{12} B_{1994,m} \\ \end{array} \right\} + \left\{ \begin{array}{l} \sum\limits_{m=1}^{12} \left( B_{1995,m} + B_{1996,m} \right) \\ \end{array} \right\} + \left\{ \begin{array}{l} B_{1997,1} \\ \end{array} \right\} \, ,$$

where  $\beta_{vm}$  is the number of births observed in month m of year y.

For subdivisions 20, 19,...,11:

$$(33) \quad \beta_{21\text{-}(i-1)} = \left\{ \quad \frac{B_{1994,i}}{2} + \sum_{m=i+1}^{12} B_{1994,m} \quad \right\} + \left\{ \sum_{m=1}^{12} \left( B_{1995,m} + B_{1996,m} \right) \right. \\ \left. \left. + \left\{ \left( \begin{array}{c} i-1 \\ \sum \\ m=1 \end{array} B_{1997,m} \right. \right) + \frac{B_{1997,i}}{2} \right. \right. \right\},$$

for i = 2 to 11.

For subdivisions 10, 9, ..., 1:

$$(34) \quad \beta_{21-(i-1)} = \left(f_i B_{1994,12}\right) + \left\{ \begin{array}{c} 12 \\ \sum\limits_{m=1}^{12} \left(B_{1995,m} + B_{1996,m}\right) \end{array} \right\} + \left\{ \left(\begin{array}{c} 11 \\ \sum\limits_{m=1}^{11} B_{1997,m} \end{array}\right) + \left(1 - f_i\right) B_{1997,12} \end{array} \right\}$$

for i = 12 to 21, i.e., i - 1 = 11 to 20, where  $f_i$  is the fraction given in Text Table 3.

Text Table 3. Fractions used in the calculation of births exposed to the risk of death, for subdivisions 10 to 1

i	12	13	14	15	16	17	18	19	20	21
Subdivision no. $s = 21 - (i-1)$	10	9	8	7	6	5	4	3	2	1
$f_i$	49/62	35/62	21/62	13/62	11/62	9/62	7/62	5/62	3/62	1/62

Fractions  $f_i$  are used for i = 12 to 21. This corresponds to subdivisions 10 to 1, respectively, which are the subdivisions for the first month of life, as shown in Text Tables 2 and 3. For example,  $f_{21}$  is used in calculating the number of births exposed to the risk of death in subdivision no. 1 (which corresponds to the first day of life). In this case,  $f_{21}$  B<sub>1994,12</sub> = (1/62) B<sub>1994,12</sub> represents half of the births observed during the last day of 1994 (December 31, 1994): (0.5) (1/31) = 1/62. For i = 20, s = 2 and  $f_{20}$  B<sub>1994,12</sub> = (3/62) B<sub>1994,12</sub> represents all births observed during the last day of 1994, plus half of the births observed on the day before (December 30, 1994): (1/31) + (0.5) (1/31) = 3/62.

The assumption underlying the use of the above fractions is that births were uniformly distributed during the months of December 1994 and 1997. Similarly, the fraction 1/2 is used in Formulae (32) and (33) above under the assumption that births in the corresponding months were uniformly distributed. An alternative method was tested during the development of the SAS programs for the 1990-1992 tables. It consisted of using the exact number of births observed rather than using Sirken's fractions. Results did not differ significantly, so this alternative method was not used for the 1995-1997 publication.

# Step 2: Calculate probabilities of death

The probability of death for subdivision s was then calculated according to the following equations:

(35) 
$$q_1 = d_1/\beta_1$$

(36) 
$$q_s = d_s / \left\{ \beta_s - \sum_{k=1}^{s-1} d_k \right\}$$

where.

d, is the number of deaths in subdivision 1, and

 $d_s$  is the number of deaths in subdivision s, for s = 2 to 21.

For variance estimation, the formula from Chiang<sup>10</sup> was used again:

(37) 
$$Var(q_s) = q_s^2 (1 - q_s) / d_s$$

# 2.3.2 Stationary Population

The number of person-years in the stationary population was calculated as follows:

(38) 
$$L_s = c_s [I_s - d_s/2]$$
 for  $s = 1$  to 21,

where,

c<sub>s</sub> represents the duration of the age interval in years: for a period of one day (s = 1 to 7), c<sub>s</sub> is 1/365; for a period of one week (s = 8 to 10), c<sub>s</sub> is 7/365; for the second month of life (s = 11), c<sub>s</sub> is 357/4,015; for months 3 to 12 of life (s = 12 to 21), c<sub>s</sub> is 335/4,015;

Is is the number of persons alive at the beginning of subdivision s; and

d is the number of deaths in subdivision s.

For the first day of life, the number of deaths is usually multiplied by a factor greater than 0.5. The usual formula is:

(39) 
$$L_1 = c_1 [I_1 - (1 - f_0) d_1],$$

where

 $c_1 = 1/(365+1/3)$ , because there were on average 365 + 1/3 days in each of the years 1995, 1996 and 1997, and

 $f_0$  denotes the fraction of deaths in the first day of life (i.e., deaths within 24 hours after birth) that occurred on the calendar day following birth.

The fraction f<sub>o</sub> can be expressed as:

(40) 
$$f_0 = \delta_2 / (\delta_1 + \delta_2)$$

where

- δ, is the number of deaths in the first day of life that occurred on the day of birth, and
- $\delta_2$  is the number of deaths in the first day of life that occurred on the calendar day following the day of birth.

On average, since death in the first day of life occurs more often within the first few hours following birth,  $\delta_1$  should be greater than  $\delta_2$ . This implies that  $f_0$  should be less than 0.5 and that 1 -  $f_0$  should be greater than 0.5. The values of  $f_0$  at the Canada level were calculated to be 0.11674 for males and 0.10590 for females.

### 3. EXPLANATION OF LIFE TABLE COLUMN HEADERS

This document contains three types of life tables: infant life tables (i.e. life tables for the first year of life), complete life tables, and abridged life tables. Estimates have been generated for males and females separately for all of these tables. In the case of the infant life tables, data have been produced at the Canada level only. Complete life tables have been constructed for Canada and all of the provinces, except Prince Edward Island. Abridged tables have been derived for Prince Edward Island and the combined territories (i.e. Yukon, Northwest Territories and Nunavut) only.

### Age x column: Age interval

The major visual difference between the various life tables found in this publication lies in the age groupings for which estimates have been produced. In the case of infant life tables, age groupings are of the form [x, x+n), where the first age, x, is included in the interval while the second age, x+n, is not. In other words, the first age value indicates the number of *completed* lifetime units (in days or months). For example, the interval "0-1 day" refers to deaths that occur in the 24-hour interval starting at a live birth (stillbirths are excluded) and ending at the end of day 1 (i.e. 23 hours and 59 minutes after birth, which is reported as 23 completed hours). The interval "1-2 days" represents the interval spanning the beginning of the second day to the end of the second day of life; that is, it comprises the deaths of infants who completed the first day of life but died before completing the second day.

In the case of complete life tables, there is only one age value per line, which indicates the number of completed years lived. The intervals in this table represent the interval between two exact ages. In other words, age x represents an interval of one year, starting at the beginning of the day an individual reaches exact age x and ending at the end of the day prior to that individual's next (x+1) birthday. For example, death at age 30 years means that the death occurred on or after the 30<sup>th</sup> birthday but before the 31<sup>st</sup> birthday.

In abridged life tables, age intervals are of the form [x, x+n-1]; that is, both ages x and x+n-1 are included in the interval. For example, age interval [40, 44] comprises deaths occurring among 40 to 44 year-olds (i.e., the interval starts at age 40 and ends just before reaching the 45<sup>th</sup> birthday). Most age intervals in abridged life tables span five years. The exceptions occur in the first two rows of these tables and the last row: the first row (age 0) represents a one-year interval and the second row, a four-year interval (ages 1-4); the last row, however, is an open age interval, which comprises all deaths occurring at ages 100 and older.

# I column: Number of survivors to exact age x

This column represents an estimate of the number of persons in an initial cohort of 100,000 live births who are still alive at the beginning of each subsequent age interval (i.e. at the attainment of exact age x). The expected number of survivors, which slowly drops as the cohort ages, is assumed to depend on the age-sex-specific mortality rates experienced in 1995-1997. Progressive values of  $I_x$  are derived by the successive application of  $I_x$  mortality rates to the remainder of the original cohort of 100,000 live births still alive at the beginning of each interval.

# <code>\_dx</code> column: Number of persons dying between exact age x and age x+n

This column shows the number of persons dying in each successive age interval who were alive at the beginning of the interval. These values are obtained by first multiplying  $I_x$  by the corresponding value of  $_nq_x$  (i.e.,  $_nd_x = I_{x,n}q_x$ ). Then, after calculating all life table values using the full decimal precision provided by SAS,  $I_x$  values are rounded to the nearest integer, and  $_nd_x$  values are set equal to the difference between consecutive rounded values of  $I_x$  (i.e. Sirken's rounding method² is used, where  $_nd_x$  is ultimately assigned the value of  $I_x - I_{x,n}$ ).

# p column: Life table survival rate (or proportion surviving to age x+n)

This column represents the probability that a person exact age x will survive to reach exact age x+n, that is, the proportion of cohort survivors at the beginning of an age interval who are expected to survive to the beginning of the next age interval. The value of  $p_x$  "the proportion surviving" is the complement from 1 of  $p_x$  "the proportion dying" (i.e.,  $p_x = 1 - p_x$ ).

# $_{n}q_{x}$ column: Life table mortality rate (or proportion dying between exact age x and age x+n)

This column represents the probability that a person of exact age x will die before reaching age x+n, that is, the proportion of cohort survivors at the beginning of an age interval who are expected to die before reaching the beginning of the next age interval. This is the most important column of the life table, because it is the basis for the entire table structure. Specifically, this is the initial column in the generation of a life table (i.e. derived from the observed data), and from which other columns are derived, on the basis of interdependent relationships.

# cv(\_q\_) column: The coefficient of variation of the variable \_q\_

The coefficient of variation (cv) associated with an estimated value for a variable (such as q) is a measure used to compare the variability of that estimate. This measure is derived from the variance estimate for the value of the variable via an intermediate step. (Variance estimates for q are described in Section 2.) Once the variance for q has been calculated, the estimated standard error (se) of q is calculated simply by taking its square root:

se (q) = 
$$\sqrt{\text{var}(q)}$$
.

Thus se is a measure of variation in the same scale as q.

The following step transforms se into a coefficient of variation, which is a relative measure of variation. The formula below shows that a given se measurement will have a greater impact on a smaller g estimate than it will on a larger g value.

$$cv(q) = se(q) / q$$

The coefficients of variation in the life tables are expressed in percentages. For example, in Table 2a, q(7) for males at the Canada level has a value of 0.00012, with an accompanying cv(7) of 20.4%. This means that there is a 68% probability that the true q(7) value lies between [ 0.00012 - 0.204(0.00012) ] and [ 0.00012 + 0.204(0.00012) ], that is, between 0.00010 and 0.00014. In a similar fashion, this coefficient of variation also indicates that there is a 95% probability that the true q(7) value lies between [ 0.00012 - 2(0.204)(0.00012) ] and [ 0.00012 + 2(0.204)(0.00012) ], that is, between 0.00007 and 0.00017; and a 99% probability that q(7) is in the range of [ 0.00012 - 2.5(0.204)(0.00012) ] to [ 0.00012 + 2.5(0.204)(0.00012) ], or between 0.00006 and 0.00018.

Estimates with a coefficient of variation exceeding 33.3% are to be used with great caution, since they are highly variable. Although q estimates with coefficients of variation equal to or greater than 100.0% are published here, the coefficients of variation themselves have been suppressed.

# $_{\rm n} {\rm L_x}$ column: Stationary population (number of life years lived $\,$ in the age interval)

 $_{n}L_{\chi}$  indicates the number of life years lived by persons in the stationary population in the age interval [x, x+n). If one assumes that a) a cohort of 100,000 persons is being born every year for an indefinite period of time, b) the proportion dying in each age interval is fixed (as determined by the values of  $_{n}q_{\chi}$ ), c) deaths are evenly distributed over time within age intervals, d) there is no migration, and e) the births are evenly distributed over the calendar year, then the survivors of these successive cohorts constitute a "stationary population." The term "stationary" is used because the number of persons living in any given age group does not change over time, and the number entering any given age group equals the number leaving the group due to death or aging (i.e. passage from one age group to the next). The number of deaths each year equals the number of births, which equals 100,000. In other words, the assumptions involved imply that column  $_{n}L_{x}$  remains fixed from one year to the next and thus stationary.

The derivation of the values of  $_nL_x$  does vary at young ages, however, due to the unequal distribution of deaths throughout the youngest age intervals (i.e. there is a higher risk of death during the earlier part of these intervals and a progressively reduced risk in the later part). To compensate for this problem, at ages 0 to 4 years, the following formulae are used in the calculations of the complete life tables:

(41) 
$$L_x = I_x - (1 - F_x) d_x$$

for 
$$x = 0, 1$$

(42) 
$$L_x = I_x - (1 - F_x) d_x - (d_{x-1} - d_{x+1})/24$$
,

for 
$$x = 2$$
 to 4

where  $F_x$  represents the separation factor at age x, that is, the proportion of individuals dying in age interval [x, x+1) who have lived in excess of half the interval. (See Appendix 1 for actual  $F_y$  values used.)

At ages five years and older, it is considered sufficiently accurate to use the following approximate formula (equivalent to Equation (41) with  $F_y = 0.5$ ):

(43) 
$$L_y = I_y - 0.5 d_y$$

for x = 5 to the maximum age in the life table.

### T<sub>c</sub> column: Cumulative stationary population (total number of life years lived beyond age x)

 $T_x$  shows the total number of years lived by persons in the stationary population in the indicated age interval and all subsequent age intervals.

$$(44) T_x = \sum_{k=x}^{\omega} L_k$$

for 
$$x = 0$$
 to  $\omega$ 

where  $\omega$  is the maximum age in the life table (note: at age  $\omega$ ,  $T_{\omega} = L_{\omega}$ ).

# e column: Life expectancy at age x (average remaining lifetime)

Life expectancy at age x represents the average number of years remaining to be lived by persons surviving to exact age x, based on a given set of age-sex-specific mortality rates (such as the 1995-1997 mortality rates) from that age onwards.

Life expectancy at age x is calculated by dividing the  $T_x$  value (the total number of person-years lived at that age and subsequent ages) by the corresponding  $I_x$  value (the number of survivors at that age):

(45) 
$$e_{v} = T_{v} / I_{v}$$

Note: Following the recommenation in Chiang<sup>10</sup> to simplify the notation, the symbol  $e_x$  is used instead of  $\mathring{e}_x$  to denote full life expectancy at age x.

For example, in the 1995-1997 complete life tables for Canada (Tables 2a and 2b), the average number of years of life remaining for 60-year-old Canadian males is 19.81 years, for an average age at death of 79.81 years. The estimate for 60-year-old Canadian females is 24.06 remaining years of life (on average), with death occurring at 84.06 years (on average).

# cv(e) column: The coefficient of variation of the variable e

The variance estimation of e for the complete life tables mirrors that of the abridged tables [see Section 2, Equation (30.1)], with the following two modifications: a) in each row,  $w_x = 1$ ; b) the number of rows (N) equals 110 (for ages 0 through 109 years inclusively). Once  $var(e_v)$  is obtained,  $cv(e_v)$  is calculated in the same fashion as  $cv(q_v)$ .

For an explanation on how to interpret the  $cv(e_x)$  column, see the description for the  $cv(_nq_x)$  column: the coefficient of variation of the variable  $_nq_x$ .

### 6. APPENDICES

# **Appendix 1. Calculation of Separation Factors**

The separation factor  $F_x$  represents the proportion of individuals dying in age interval [x, x+1) who have lived in excess of half of the interval. The value is calculated as follows:

Consider all individuals who died in age interval [x, x+1) and divide them into two groups.

Group 1 consists of those individuals who died in a given year on or after their birthday. For these individuals, birth year plus age equals death year. For example, someone born in April 1935 who died at age 60 in June 1995: 1935 + 60 = 1995.

Group 2 consists of those individuals who died in a given year before their birthday. For these individuals, birth year plus age equals death year minus 1. For example, someone born in April 1935 who died at age 60 in January 1996: 1935 + 60 = 1996 - 1.

Then,  $F_x = g_{2x} / (g_{1x} + g_{2x})$ , where  $g_{kx}$  is the number of deaths at age x in death group k during the 1995-1997 period.

Tables A1 and A2 present a list of the separation factors at ages 0 to 4 years used in the calculation of the 1995-1997 life tables. Complete life tables use separation factors for each age from 0 to 4 years, while abridged life tables use one separation factor at age 0 and another one for age 1-4 years. Furthermore, as explained in Section 2.2, regional separation factors were calculated for the 1995-1997 tables (the 1990-1992 tables used provincial separation factors). In addition, these separation factors exclude areas with small counts (PEI and the territories) for the detailed life tables, but include them for the abridged life tables.

Table A1. Separation Factors by Region, Sex and Age - Complete Life Tables

# Appendix 2. Calculation of Life Table Mortality Rates at Ages 0 to 4 years in the Complete Life Tables

From section 2.1.1, recall that q was calculated as

(6) 
$$q_x = 1 - (P_x' / E_x) (E_{x+1} / P_x'')$$
  
for x = 0 to 4 years.

In order to explain this formula, define the following terms:

- $E_x^z$  is the number of persons attaining age x in calendar year z,
- $P_x^z$  is the number of persons living at the beginning of year z who are age x years,
- $D_x^z$  is the number of persons dying in year z at age x,
- $_{\alpha}D_{x}^{z}$  is the number of persons dying in year z at age x who attained age x in year z (their year of birth is z x); this corresponds to death group 1 mentioned in Appendix 1,
- $_{\delta}D_{x}^{z}$  is the number of persons dying in year z at age x who attained age x in year z 1 (their year of birth is z x 1); this corresponds to death group 2 mentioned in Appendix 1.

Three important relationships follow from the previous definitions:

(46) 
$$D_x^z = {}_{\alpha}D_x^z + {}_{\delta}D_x^z$$

(47) 
$$E_x^z = P_x^{z+1} + {}_{\alpha}D_x^z$$

(48) 
$$E_{x+1}^z = P_x^z - {}_{\delta}D_x^z$$

The population counts  $P_x^2$  and  $P_x^2$  are known; they are the January 1 population estimates by age and sex from Demography Division, Statistics Canada. The population counts of those who lived to exact age x in the period 1995-1997,  $E_x$  and  $E_{x+1}$ , were then calculated as follows. For example, as of January 1, 1995, there was an estimated population of 186,608 females in Canada age 0 years (i.e. they were born in 1994 and they survived past the end of December 31, 1994). This count is derived from the 1994 count of live births, from which is subtracted the deaths and emigrations and to which is added the immigrations for this birth cohort. Thus  $P_0^{1995}$  = 186,608.

Then, given that there were 22 females in Canada who were born in 1994 but who died in 1995 before they reached their first birthday, that is  $_{\delta}D_{0}^{1995}$  = 22, we can use Equation (48) to get:

$$E_1^{1995} = P_0^{1995} - \delta_0^{1995}$$

$$= 186,608 - 22$$

$$= 186.586$$

as the estimated number of females who attained age 1 in 1995.

This procedure is continued until all needed  $E_x^z$  values are obtained.

For the 1990-1992 life tables, the approach was taken to start with actual birth counts for the  $E_0^z$ , and then, with death counts, estimate the needed  $P_x^z$ s and subsequent  $E_x^z$ s. Appendix 2 of that publication shows how this was done<sup>3</sup>. But that approach did not take migration into account, and the result was that each year's births died off in succeeding years, e.g.:

$$E_0^{1994} \ge P_0^{1995} \ge P_1^{1996} \ge P_2^{1997} \ge \dots$$
 (etc.)

But actual January 1 population estimates showed instead that

$$P_0^{1995} < P_1^{1996} < P_2^{1997} < \dots$$
 (etc.)

Moreover, the Statistics Canada series of January 1 population estimates account for migration.<sup>1</sup>

Therefore, for the 1995-1997 life tables, the observed  $P_x^z$ ,  ${}_{\alpha}D_x^z$  and  ${}_{\delta}D_x^z$  were used, and then  $E_x^z$  were estimated from these.

Next, from the previous definitions, the life table mortality rates based on a one-year period would be calculated as  $q_x = 1 - (P_x^{z+1} / E_x^z) (E_{x+1}^z / P_x^z)$ . But since mortality rates from a three-year period (1995-1997) are desired, the following are first defined:

- E, the number of persons who attained age x during the period 1995-1997,
- $E_{x+1}$  the number of persons who attained age x+1 during the period 1995-1997,
- P'<sub>x</sub> the number of persons who attained age x during the period 1995-1997 and who were alive at the end of the year in which exact age x was attained,
- P<sub>x</sub> the number of persons alive at the end of the calendar year in which age x was attained and whose (x+1)<sup>th</sup> birthday falls in the period 1995-1997.

It then follows that

(49) 
$$E_X = \sum_{z=1995}^{1997} E_X^z = \sum_{z=1995}^{1997} (P_X^{z+1} + {}_{\alpha}D_X^z)$$

(50) 
$$E_{X+1} = \sum_{z=1995}^{1997} E_{X+1}^{Z} = \sum_{z=1995}^{1997} (P_X^{Z} - \delta D_X^{Z})$$

(51) 
$$P_X' = \sum_{z=1995}^{1997} P_X^{z+1}$$

(52) 
$$P_X'' = \sum_{z=1995}^{1997} P_X^z$$

In the above equations,  $E_x^z$  is defined for x = 0 to 4 and z = 1995 to 1997. Variance estimation followed that used for other age groups:

$$var(q_x) = q_x^2 (1 - q_x) / (Q_x^2 + D_x^2)$$

But note that there was no averaging of death counts in the denominator over the 3-year period. Whereas in Section 2.1.2 a 3-year average of death counts was used to replace a single year death count in the denominator of the central death rate  $m_{\chi}$ , in this estimation the 3-year totals are kept, and no averages are used to replace a single year's count.
